Understanding the mass assembly of galaxies at $0 < z < 4$: Spitzer's contribution and open questions

We will present the main results of our research about the assembly of galaxies at $z < 4$ based on the data obtained by the deepest Spitzer surveys carried out with IRAC and MIPS during the cryogenic mission. These data in the near-, mid- and far-IR have allowed us to obtain unprecedentedly robust estimations of the obscured SFRs and stellar masses of distant galaxies. Analyzing SFR and stellar mass functions in several redshift bins at $0 < z < 4$, we have found and quantified that galaxies formed following a downsizing scenario, with the most massive systems assembling early in the lifetime of the Universe and very quick (i.e., with very high star formation efficiencies, and a significant amount of obscured starbursts), while less massive systems assembled later and/or more slowly. However, Spitzer has left several open questions that still hamper our current understanding about the formation and evolution of galaxies. I will discuss three of these results and how future facilities such as Herschel, ALMA, E-ELT or JWST can lead to a more robust and detailed (with higher spatial resolution and depth) characterization of how galaxies formed in the early Universe: (1) the mid-to-far IR colors of galaxies evolve with redshift, departing considerably from the typical values observed in the local Universe, specially at $z > 1.5$ -2.0; (2) the IMF might not be universal, evolving to a top-heavy IMF at $z > 1.5$; (3) obscured AGN may be ubiquitous in high- z galaxies, playing a significant role in the downsizing scenario.

Understanding the mass assembly of galaxies at $0 < z < 4$: *Spitzer's* results and open questions

Some conclusions and open questions

Extreme Starbursts in the Local Universe
Granada, June 21-25, 2010

Some conclusions and open questions

- Galaxy formation follows a **downsizing scenario**. Most massive galaxies collapsed first, (almost) **monolithically** (early and quick) at $z > 1.5-2.0$ (some are already dead by that epoch). Coalescence probably more important in less massive systems (**hierarchical scenario**), which assembled more slowly (and later).

Some conclusions and open questions

- Galaxy formation follows a **downsizing scenario**. Most massive galaxies collapsed first, (almost) **monolithically** (early and quick) at $z > 1.5-2.0$ (some are already dead by that epoch). Coalescence probably more important in less massive systems (**hierarchical scenario**), which assembled more slowly (and later).

Challenge for models!!!

Coalescence probably more important in less massive systems (**hierarchical scenario**), which assembled more slowly (and later).

Challenge for models!!!

- Most massive galaxies ($M > 10^{11} M_{\odot}$) **increased their mass from SF alone** by up to a factor of 2 (spheroids) and 4 (disks) from $z \sim 2$. In contrast, spheroids **increased their size x6** and disks **x3**. Mergers? Wrong sizes?

Some conclusions and open questions

- **High- z ULIRGs are not like local ULIRGs!!!**: the dust emission is different (warm vs. cold dust ratio, PAH abundance/prominence), maybe obscured AGN are important (hot dust component on top), the sizes of the star-forming regions are larger (?).
